ABSTRACT
Grafting in brinjal is an alternative technology for chemical treatments to control soilborne pathogens with minimum impact on product quality and environment. The present study was carried out to determine the graft compatibility of brinjal scions (Dhruva and CO 2) with five wild Solanum rootstocks and their growth performance in open field condition. The cleft grafting method was adopted in this study. The non-grafted plants were used as control under open field condition. Solanum torvum recorded less number of days for graft union with Dhruva (10.36) and CO 2 (10.54) followed by Solanum capsicoides and Solanum chrysotrichum. The results on grafting success at
30 days after grating revealed that the highest success percentage was observed in Dhruva (83.42%) and CO 2 (82.08%) grafted with Solanum torvum rootstock followed by Solanum capsicoides and Solanum chrysotrichum. The field survival rate was higher in Dhruva (88.75%) and CO 2 (85.20%) grafted onto Solanum torvum followed by Solanum capsicoides and Solanum chrysotrichum. Dhruva (90.52cm, 9.15) and CO 2 (80.17cm, 7.29) grafted onto Solanum torvum recorded maximum plant height and more number of primary branches per plant respectively followed by Solanum chrysotrichum. Though Solanum capsicoides performed well throughout the grafting process their growth performance was poor in open field condition. Hence Solanum torvum followed by Solanum chrysotrichum could be used as compatible rootstock for grafting with brinjal scions.

Keywords: Grafting; rootstock; scion; brinjal.

1. INTRODUCTION

Brinjal (Solanum melongena L., 2n = 24) belonging to the family Solanaceae is a native crop of India with China as its secondary center of origin [1]. It is a warm-season crop, adapted to a wide range of climatic conditions of the country. Brinjal finds its place as the poor man’s vegetable in Indian curries. Furthermore, brinjal is a region-specific crop where consumer acceptance is based on their preference for color, shape and taste suited for their specific locality [2].

Despite the high economic importance the major constraint in brinjal production is their susceptible nature to soil borne diseases, pests and nematodes which results in heavy yield loss [3]. With few resistant varieties and region-specific preference nature by consumer, grafting has become an alternate approach in brinjal to mitigate the yield loss [2]. Grafting brinjal cultivars with perennial and wild Solanaceous species as rootstock, proved to increase the yield and long availability period of the fruits through ratoon crop [4]. Grafting is also highly effective in ameliorating crop losses caused by adverse environmental conditions [5]. Hence proper selection of rootstock with resistance to biotic and abiotic stress can provide perennially nature along with disease and pest free plants, increased yield and fruit quality [6,7]. Thus, the aim of this study was to identify the compatible rootstock for grafting with brinjal based on the success percentage of graft combination, field survival rate and their growth performance in open field condition.

2. MATERIALS AND METHODS

The experiment was conducted in College Orchard, Department of Vegetable Science, HC & RI, TNAU, Coimbatore during 2021-22. The experimental materials for the present study comprised five wild Solanum species namely Solanum capsicoides, Solanum chrysotrichum, Solanum sisymbriifolium, Solanum violaceum and Solanum torvum as rootstocks and two cultivated brinjal namely Dhruva and CO 2 a cultivar from Tamil Nadu Agricultural University were used as scion for grafting.

2.1 Grafting

Grafting was performed in the rootstock which attained pencil-size stem thickness and 35 days old scion seedlings. The grafting method adopted in this experiment was cleft grafting [8]. Grafting was done under greenhouse condition during morning and evening hours. Immediately after grafting the plants are covered with 1000 gauge polythene bag and transferred inside the mist chamber to maintain optimum humidity (RH >95%) and temperature (25-30° C). The plants were kept inside the mist chamber for seven days to form a successful graft union (Fig. 1). Once the scion started sprouting the polythene cover was removed and the plants were transferred to shade net condition for five to seven days. After acclimatization, the plants were transplanted into the open field. The grafting experiment under the greenhouse followed Completely Randomized Design (CRD) with three replications. Graft compatibility was assessed in terms of Number of days taken for graft union and graft success percentage at 15 and 30 days after grafting (DAG). While open field condition followed Randomized Block Design (RBD) with three replications including 10 plants for each replication. The observations viz., field survival rate at 30 days after transplanting (DAT), plant height at 90 days after transplanting (DAT) and No. of primary branches per plant at 90 days after transplanting (DAT) were recorded in open field (Table 1).

2.2 Statistical Analysis

The analysis was carried out using the statistical software SPSS v.25; Data were subjected to
analysis of variance (ANOVA) at two significant levels (P<0.05 and P<0.01) and critical difference (CD) values were calculated each time.

3. RESULTS AND DISCUSSION

The graft compatibility study indicated that grafting Dhruva (10.36) and CO 2 (10.54) grafted onto *Solanum torvum* recorded significantly faster graft union followed by Dhruva (10.95) and CO 2 (11.03) grafted onto *Solanum chrysotrichum* through cleft grafting. These findings were in line with Sherly [9] and Kumar et al. [10] that *Solanum torvum* recorded minimum number of days for graft union compared to other rootstocks. Rasool et al. [11] reported that graft union is the key factor for grafting success and further growth of the plant. Graft union is associated with cohesion between rootstock and scion (i.e., callus formation, vascular bundle differentiation and connectivity at the graft interface) that insures the balanced development of both scion and rootstock [12]. Hence the process of graft union and wound healing might be faster in *Solanum torvum* and *Solanum chrysotrichum* than other species.

Dhruva (17.52) and CO 2 (18.36) grafted onto *Solanum sisymbriifolium* recorded maximum number of days for graft union. Similar results reported that *Solanum sisymbriifolium* took maximum number of days for graft union with Bhangor (24.05 days) through cleft grafting method and complete failure of grafts found during 30 DAG [13]. In addition to that Pugalendhi et al. (2021) reported that TNAU tomato hybrid CO3 and Shivam grafted on *Solanum torvum* took the least number of days for graft union (9.5 days) while *Solanum sisymbriifolium* and *Solanum capsicoides* did not show vascular connection on 21 days of grafting. It took more time for graft union. Failure in graft union may be due to lack of cellular recognition, interference in the wounding response or incompatible toxins which forms distorted unions and eventually leading to graft failure [14].

DAG – Days after grafting; DAT – Days after transplanting
(Figures in parentheses are arc sine transformed values)
From the Table 1 it is evident that Dhruva (90.32%, 83.42%) and CO 2 (89.17%, 82.08%) grafted onto Solanum torvum recorded the highest grafting success percentage at 15 DAG and 30 DAG followed by Solanum capsicoides with Dhruva (87.43%, 81.62%) and CO2 (85.36%, 79.21%) and Solanum chrysotrichum with Dhruva (85.11%, 80.71%) and CO 2 (83.46%, 79.14%) respectively. The success of a graft combination is determined by cell division at the graft union site followed by formation of new vascular connection as reported in grafted bitter gourd by Tamilselvi and Pugalendhi [15].

Grafting success percentage was recorded the lowest in Solanum violaceum when grafted with Dhruva (78.94%, 57.89%) and CO2 (70.83%, 53.12%). This is confirmed by high mortality rate of the plants during the experiment at 15 DAG and 30 DAG.

Among the five rootstocks used for grafting, Dhruva (88.75%) and CO 2 (85.20%) grafted onto Solanum torvum recorded the highest survival rate under open field condition followed by Dhruva (83.45%) and CO 2 (81.03%) grafted onto Solanum capsicoides and Dhruva (81.67%) and CO 2 (79.43%) grafted onto Solanum chrysotrichum. Significantly lower survival rate was observed in Dhruva (51.73%) and CO 2 (38.82%) grafted onto Solanum sisymbriifolium as shown in Fig. 2. (Average on performance of rootstock).

The findings were in line with Sherly [9] that Solanum torvum grafted onto COBH 2 recorded high survival rate and robust growth of the plant in open field and Dhivyra (2013) when Solanum torvum grafted on tomato recorded better growth and survival followed by Solanum incanum. The establishment of wound repair mechanism between scion and rootstock might have contributed in recording high survival rate after transplanting.

While Tamilselvi (2013) reported that lower survival rate might be caused by anatomical mismatching, resulting in the misalignment of cambial regions of rootstock and scion. This misalignment led to tissue death in the wounded areas of the rootstock, scion and subsequent scion death. Similar findings by Mahbou et al. [16] and Survve et al. [17] reported that, despite the high graft success percentage at nursery level, lower survival rate in open field condition might be due to the availability of more congenial conditions in the establishment of seedlings/grafts under nursery condition.

The mean performance of plant is considered as the key parameter to assess the potential of different graft combinations under open field condition. The analysis of variance for the grafted plants exhibited significant differences for plant height and number of primary branches per plant than non-grafted plants. The morphological parameters especially plant height and number of primary branches per plant were substantially better for most of the grafted combinations than non-grafted control as shown in Table 1. Vigorous plant growth was observed in most of the grafts, as reflected in maximum plant height and more no. of primary branches per plant than non-grafted plants. This could be attributed by larger and vigorous root growth of the rootstock which ensured better plant height and vigorous growth through absorption of optimal level of water and nutrients (Musa et al., 2020).

The maximum plant height was recorded in Dhruva (90.52cm) and CO 2 (80.17cm) grafted onto Solanum torvum followed by Solanum chrysotrichum with Dhruva (85.53cm) and CO2 (76.05cm) and Solanum violaceum with Dhruva (81.59cm) and CO 2 (73.67cm). Though grafting success percentage and survival rate was higher in Solanum capsicoides, it recorded poor growth in open field condition. This might be due to the morphology of the rootstock which grows only 0.50-1m in height (herbaceous shrub) [18]. The result showed that the vigor of the rootstock is essential in conferring scion vigor. Gisbert et al. [4] reported that vigorous root system of the rootstock enhances the ability to absorb water and nutrients compared to the non-grafted plants while serving as a better supplier of endogenous plant hormones. Similarly rootstocks has varying levels of GA3 which cause differences in vegetative growth and vigor of scion in grafted plants [19].

Similarly, Dhruva (9.15) and CO 2 (7.29) grafted onto Solanum torvum recorded higher number of primary branches per plant followed by Solanum chrysotrichum with Dhruva (8.51) and CO2 (7.27) and Solanum violaceum with Dhruva (8.19) and CO 2 (7.05). The effect of rootstock on the mineral content in the aerial portion of the plant may be related to the physical properties of the root system, such as lateral and vertical development. This may lead to improved uptake of water and minerals, thereby resulting in a greater number of branches in grafted plants [20]. While number of primary branches per plant was lower in Dhruva (4.07) and CO 2 (3.50) grafted onto Solanum capsicoides.
Sherly [9] reported that brinjal grafted onto *Solanum torvum* exhibited maximum plant growth than non-grafted plants. Similar findings were reported by Dhiiva (2013) and Bharathi et al., (2021) when tomato was grafted to *Solanum torvum*.

Though *Solanum violaceum* performed well under open field condition with low grafting success percentage Dhiiva et al. [21] reported that this species is highly susceptible to root-knot nematode infestation. Hence this species can be narrowly used in areas where root-knot nematode infestation is devoid. Whereas *Solanum torvum* is highly resistant to root-knot nematode and exhibited high grafting success percentage with field survival capacity [22-24].

**4. CONCLUSION**

The results shows that grafting in brinjal can contribute to significant improvement in production and provide resistance to soilborne pathogens and diseases or to enhance the vigor of the scion. Grafting of CO 2 and Dhrueva with five wild *Solanum* rootstocks revealed that *Solanum torvum* exhibited less no. of days for graft union, higher graft success percentage, field survival rate, plant height and no. of primary branches per plant. Though *Solanum capsicoides* recorded higher graft success percentage and field survival rate than *Solanum chrysotrichum*, it exhibited poor growth performance in open field condition. Finally the result of the study indicated that *Solanum torvum* and *Solanum chrysotrichum* can be the most compatible rootstock for brinjal grafting. The study can be extended to select rootstocks and resistant species which allow production in infested soils.
